Abstract

This work creates and verifies a mathematical model for modifying soft-leaved wood by impregnation and compaction. The relevance of this work is because due to global climate change, recently there has been a change in the average formula of the species composition of many forests of the temperate zone of Eurasia: soft-leaved wood species replace the coniferous forests of natural generation. The change in species composition is aggravated by the active spread of plantation growing of forests, because soft-leaved wood species are more suitable for plantation growing. One of the most promising areas for processing soft-leaved wood, including those grown by plantation, is the modification of such wood by impregnation and compaction. The main technological processes of obtaining modified wood with the achievement of specified parameters and properties is the dehydration of samples impregnated with various compositions with simultaneous pressing and drying. As a result of the implementation of the developed mathematical model, an equation of linear multiple regression is obtained depending on the sample processing time on the required values of their compaction and humidity in a given temperature field, which forms a reliable theoretical basis for solving various optimization problems of the technological parameters of the pressing and dewathering plasticized wood samples.

Keywords: agricultural engineering; wood; drainage; pressing; optimization

Introduction

All over the world, including in Eurasian forests, significant changes are observed, primarily due to a change in the average formula of the species composition in favor of soft-leaved wood species, which replace the coniferous forests of natural generation (Irland et al., 2001; Brunt et al., 2006). The problem of changing the natural coniferous plantations with soft-leaf subsequent generations is connected with both natural and economic factors. Natural factors include, above all, a shorter duration of the age class and, accordingly, a higher growth rate of soft-
leaved wood species, compared with conifers. Economic factors are related to the fact that soft-leaved wood is in low demand at woodworking enterprises (Bollmus et al., 2017; Mokhirev et al., 2018). Soft-leaved woods are practically not used for the manufacture of structural timber. On the other hand, there are some examples of the effective use of soft-leaved wood for the production of furniture blanks, wood-based panels, and fuel (Pettinari et al., 2017). The ever-increasing distance of the removal of harvested wood more and more raises the question of growing fast-growing tree species by the plantation method, followed by efficient processing into sought-after products (Vagveldi et al., 2016; Bobar & Winder, 2017). One of the most promising areas for processing soft-leaved wood, including those grown by plantation, is the modification of such wood by impregnation and compaction. The main technological processes of obtaining modified wood with the achievement of specified parameters and properties is the dehydration of samples impregnated with various compositions with simultaneous pressing and drying (Shamaev, 2003; Bollmus et al., 2017). In this work, it was developed a mathematical model of drying with pressing pre-impregnated with various wood compositions. In this model, the criterion of optimization and the target was the achievement of high quality indicators with the least expenditure of energy. It should be noted that in addition to the quality indicators achieved by optimizing the processing of soft-leaved wood, an important aspect is the energy intensity of these processes, which, especially recently, is becoming a matter of paramount importance in logging production (Gustavsson & Sathre, 2006; Bribián et al., 2011; Grigoriev et al., 2014).

Materials and Methods

Table 1 shows the values of α.10⁶ (1/deg) (the coefficient of linear expansion of wood, which characterizes the increase in the unit length of the material when heated by 1°C) across the fibers in the radial and tangential directions for three wood species (Ugolev, 2001).

As follows from the data Table 1, for different types of wood, the coefficient α is observed in different directions across the fibers. Along the fibers, similar indicators are 7 to 10 times less than the data in Table 1, i.e. the temperature factor is more significant when pressing wood samples across the fibers.

In Table 2, based on experimental data (Shamaev, 2003), the values of $E_1$ and $E_2$ for urea samples of birch of different humidity $W$, plasticized with urea, are presented. Note that depending on the value of $W$, the ratio, $E_1/E_2$, for example, in the radial direction, changes 1.7-4.7 times. In the same relation, at constant pressure, the deformations of $ε_2$ to $ε_1$ will also differ, however, it is generally wrong to neglect instantaneous elastic deformations.

Results and Discussion

Considering the results of the factor analysis of the influence of pressing indicators on the properties of modified wood (Shamaev, 2003), let us take as the criterion of the efficiency of technological processes the final density $\rho$ of the sample (or its relative compaction $\bar{\rho} = \rho/\rho_0$, where $\rho_0$ is the initial density of the impregnated wood before pressing) at a given degree $\bar{W}$ of its dehydration, i.e. reduce the initial moisture content $W$ to the required level.

Let us consider the scheme of the applied technology of pressing rectangular samples of wood impregnated with moisture and saturated with a flat die $l$ without using molds (Fig. 4, Fig. 1a). Let us assume that pressing a layer $h$ of wood sample 2 with height $H$ and width $b$ is carried out across the fibers in the radial direction (direction of force $P$) with simultaneous drying in a given temperature field $T$.

The degree of pressing of the sample or the value of the total longitudinal strain $\varepsilon$ is related to the value $\bar{\rho}$ by ratio:

$$\bar{\rho} = \varepsilon + 1.$$  

In this case, the condition for effective deformation of the sample without increasing its width $b$ and destruction of wood 2 elements up to the specified values of pressing is the following requirement (Shamaev, 2003): during the necessary and sufficient time interval $t_0$ effective dewatering of the wood sample, pressing is carried out at such a speed of $V_c = h/\tau$, at which the total value of the total transverse strain $\varepsilon_y$ of the marginal zone of sample 3 coincides with the amount of shrinkage strain $\varepsilon_y$ across the fibers in the tangential direction, i.e. the condition is fulfilled:

$$\varepsilon_y = \mu\varepsilon = \frac{\varepsilon}{(1 - \nu)}\varepsilon_y = \varepsilon_y.$$  

$$V_c \cdot V_y \varepsilon = \varepsilon_y.$$  

The relation (2) denotes: $\mu$ – the coefficient of lateral expansion, $\nu$ – Poisson’s ratio, $\varepsilon$ is the total longitudinal deformation of the medium in the direction of pressing.

In practice, the specified range of pressing is mainly $\varepsilon = 0.4–0.6$, however, in some cases, the value of $\varepsilon$ exceeds the upper limit of this range. Taking into account that the deformation of the sample occurs in the field of high temperatures (up to 140–170°C), relations (1) and (2) need to be refined, since temperature deformations $\varepsilon_T$ and shrinkage deformation $\varepsilon_{sh}$ have an additional effect on the values and $\varepsilon_T$.

We assume that in a sample of wood heated to temperature $T$, temperature deformations $\varepsilon_T$ act and the material experiences a corresponding internal pressure of $P_T$ equal to (Parston, 2010):

$$P_T = E\varepsilon_T = \frac{\alpha E T}{2(1 - \nu)},$$  

where $E$ is Young’s modulus, $\alpha$ is the coefficient of linear expansion of wood, which characterizes the increase in the unit length of the material when heated by 1°C.

Under the action of a compressive load $P$, the layer $h$ experiences a vertical $q_v$ and a horizontal $q_h$ of pressure, equal to (Shapiro et al., 2006):

$$q_v = \frac{Eh}{R\arctg\left(\frac{H-h}{R}\right)},$$  

where $R$ is the stamp parameter:

$$R = \frac{2b(1 + \frac{b}{H})}{\sqrt{\pi}}, \mu = \frac{\nu}{(1 - \nu)}.$$  

In relation (4): $\mu$ is the lateral expansion coefficient, $\nu$ – Poisson’s ratio, $E$ is Young’s modulus.

The deformation of an arbitrary element of the medium can be described by generally accepted models (Blend, 1965).
In (Shamaev, 2003), the Maxwell and Burgers models with two values of stress relaxation time $t_0$ were used to study the deformation of impregnated wood. It is noted that elastic deformations in wood are determined by the presence of cellulose, and inelastic ones by lignin and hemicelluloses. For oak samples, the $\tau_0$ values $t_0$ for instantaneous elastic deformation are 14.35 s, for long-term deformation – 53.14 s. For birch samples, these figures are respectively 11.19 and 61.98 s.

The generalized four-element Voigt model (Fig. 1b), according to (Blend, 1965), describes well the process of deforming nitrocellulose without a successively attached first spring with an $E_1$ modulus of instantaneous elasticity thus, it is believed that the effect of instantaneous elastic deformations $\varepsilon_1$ can be neglected in comparison with long $\varepsilon_2$:

$$\varepsilon_1 = \frac{q_v}{E_1}, \quad \varepsilon_2 = \frac{q_k}{E_2},$$

where $E_2$ is the modulus of long-term elastic deformation.

The same model was used in the analysis of the processes of static compression by flat stamps of soil-grounds penetrated by the root tree system (Shapiro et al., 2008). It is shown that when describing the process of compacting the medium, it is advisable to combine two elastic elements into one with a common modulus of elastic deformation (Young’s modulus) $E = E_1 + E_2$, i.e. the total elastic deformation in the deformation sections $A$ and $B$ (Fig. 1b,c) is the sum:

$$\varepsilon = \varepsilon_0 + \varepsilon_p.$$  

Viscoplastic deformation $\varepsilon_p$, manifested in areas $B$ and $C$, based on the results of research (Shapiro et al., 2008) can be defined as:

$$\varepsilon_p = \frac{E_1}{E_2} \left(1 - \exp \left(-\frac{t}{t_i}\right) \left(\ln \frac{H}{h} + 1\right)\right)$$

where $t_i$ is the lag time for the Voigt element, equal to the ratio of the viscosity $\eta$ of the medium to the elastic modulus $E_2$ of the second spring.

Analysis of the creep curves $\varepsilon(t)$ of nitrocellulose heated to 90°C (Blend, 1965), as well as birch samples (Shamaev, 2003) impregnated and heated to 99°C at different humidity values ($W = 5–20\%$) and compression pressure ($q_c = 1.8–8$ MPa) showed that the value of $t_i$ can exceed 300 s, and under certain conditions it reaches 600 s.

Since the value of $G$, the inverse of the elastic modulus $E$, is the elasticity of the elastic spring, in our case the time lag $t_i$ is the product and the more viscous the medium, the larger the value of $t_i$.

$$t_i = \eta G = \eta/E_2$$

An increase in viscosity can be due to both an increase in the coefficient $\eta$ and a decrease in the modulus of long-term elastic deformation $E_2$. With regard to the pressing process of impregnated wood, in particular urea (carbamide); this is achieved by increasing the percentage of plasticizer and its heating temperature.

During the entire period of deformation of the layer $h$ in section $B$ of stress growth $\sigma$ and in section $C$, where $\sigma = \text{const}$ (Fig. 1c), the total strain $\varepsilon$ in the direction of pressing is estimated as the sum of elastic and viscoplastic deformations, i.e.

$$\varepsilon = \varepsilon_0 + \varepsilon_p.$$  

Let us note one more circumstance. In the process of drying wood, as its moisture content $W$ decreases, the $E_i$ indices increase, i.e. the elasticity of elastic elements in the Voigt model decreases and the retardation time decreases, which must be taken into account when estimating $\varepsilon_p$ using relation (7).

Let us compare data in Table 2 with data in Table 3, obtained by determining the Young’s modulus $E$ for various natural wood species at $W = 15\%$.

Summing up the indicators $E_1$ and $E_2$ in Table 2 and extrapolating linearly the obtained value of $\dot{E}$ by the moisture index $W = 15\%$, we compare the result with the generalized index $E$ from Table 3. As a result, it can be concluded (by the example of birch samples) that the plasticization of wood leads to a tendency to increase the total modulus of elastic deformation $E$.

When the pressing wood, saturated with moisture to a depth $h$, is considered (Fig. 1a) an elastic filtration body, it is assumed that both the initial spring 4 and the compressed spring 5 of two combined elastic elements (Fig. 1b) contain micro holes through which fluid flows out according to the linear Darcy law (Kolesnikov et al., 2019).

As such holes (the main water-carrying elements of wood) take vessels or tracheids with a certain density of their placement of $N_c$ (pieces per 1 mm² sample surface) and diameter $d_c$ (μm). In particular, for birch (as a whole along the trunk), these values are $N_c = 98$ pcs/mm² and $d_c = 58$ μm, respectively.

We will assume that as the wood layer is pressed and the total longitudinal strain $\varepsilon$ increases, the channel diameter $d_c$ decreases in proportion to 1-ε. Based on the methodological provisions, the condition is fulfilled in a fully saturated wood moisture:

$$q_v = p_w + p_{fl}$$

where $p_w$ is the pressure in the wood, and $p_{fl}$ is the pressure in the liquid.
The value of \( p_w \) is determined by the values of the pressure of the vertical displacement \( h \) and the temperature expansion of the \( P_r \):

\[
p_w = \frac{h}{H}E + P_r \tag{11}
\]

Performing the necessary transformations, by analogy with (Chibirev et al., 2019), we obtain the integral-differential equation for the speed \( V_f \) of the immersion of the stamp:

\[
\frac{1}{4\gamma}b^2C_{sv}k_p \frac{d\ln V_f}{dt} = -\left(q_v + E + P_r\right) + 2\frac{E}{h_o}V_f dt, \tag{12}
\]

where \( C_{sv} \) is the specific volume of the pore space in the volume of wood occupied by the liquid; \( k_p \) is the permeability coefficient of the medium (cross-sectional area of the channel of the porous medium through which the fluid is filtered); \( \gamma \) dynamic fluid viscosity.

\[
s_c = \pi d^2/4. \tag{13}
\]

The speed \( V_f \) is related to the velocity \( V_{pr} \) of the outflow of fluid through the spring holes by the integral relation (Chibirev et al., 2019):

\[
V_f = \frac{C_{sv}V_{pr}b}{2(h - \int V_{pr} dh)}. \tag{14}
\]

The speed \( V_{pr} \) is related to the velocity \( V_{pr} \) of the outflow of fluid through the spring holes by the integral relation (Chibirev et al., 2019):

\[
V_{pr} = \frac{C_{sv}V_n}{2(H-h)} \exp \left(-\left(q_v + E + P_r\right)4k_r t \right). \tag{15}
\]

Determining \( V_{pr} \) from (15), let us calculate the time to relaxation of dehydration during the outflow of a fluid within the layer \( h \) as:

\[
t_0 = \gamma \left(4b^2C_{sv}k_r \right) \tag{16}
\]

Then the size \( d_{sh} \) of the marginal area in layer \( h \), in which the wood will dehydrate during the time \( t_0 \), is:

\[
d_{sh} = V_{pr}t_0. \tag{17}
\]

The degree (percentage) of dewatering \( \bar{w} \) of the sample within its width \( b \) will be (Shamaev, 2003):

\[
\bar{w} = \frac{2d_{sh}}{b}. \tag{18}
\]

The requirement to fulfill relation (2) in the process of pressing the layer \( h \) of wood dictates the need to determine the amount of deformation of shrinkage \( \varepsilon_{sh} \). The value of \( \varepsilon_{sh} \) depends on the coefficient of shrinkage of the wood \( K_{sh} \) and the degree of dehydration:

\[
\varepsilon_{sh} = K_{sh}\bar{w}. \tag{19}
\]

As follows from the data analysis Table 4 \( K_{sh} \) value varies in a fairly wide range of values, with shrinkage in the tangential direction for coniferous woods on average 1.7-1.8 times greater than shrinkage in the radial direction, whereas for hardwood this ratio decreases to 1.2-1.6.

Thus, it is advisable to press the wood in the direction of minimum shrinkage. If this factor can be considered insignificant for birch specimens, it is essential for other breeds (Tambi et al., 2017).

The purpose of the implementation of the adopted method of dewatering during the process of pressing and drying wood is to provide such conditions under which relation (2) is fulfilled and a sample is obtained with a given density and strength without the formation of cracks and defects.

Wood will be pressed cyclically in two stages:

- at the first at \( 0 \leq t \leq t \), the pressing pressure \( q_v \) increases to the maximum value in accordance with the given speed \( V_{pr} \);
- at the second, when \( t < t \leq t_0 \), the pressing pressure is kept constant at the reached level.

The combination of relations (1)-(19) is the basis of a mathematical model of pressing samples of impregnated wood with their simultaneous drying. Calculations using these ratios were performed for pressing across the fibers in the radial direction under a flat press of specimens of heated moist birch impregnated with 10-20% aqueous urea solution, with the following initial data: \( V_{pr} = 1.4 \text{ mm/min}, \alpha = 33.710^{-6} \text{ (1/degree)}, \ W = 50\%, \rho = 760 \text{ kg/m}^3, \ E_1 = 126.9 \text{ MPa}, E_2 = 101.5 \text{ MPa}, v = 0.3, T = 140°C, E_1/E_2 = 4, b = H = 0.13 \text{ m}, K_{sh} = 0.26, s_c = 0.00264 \text{ mm}^2.

In Fig. 2 for the first pressing stage, the dependences \( q_v(h) \) and \( t_0(h) \) are presented. As you can see, there is a linear increase in the values of \( q_v \) and \( t_0 \) with increasing \( h \). At the end of the first pressing stage (\( t = 60 \text{ s} \)), the values of \( q_v \) were 1.506 MPa and the necessary and sufficient dehydration time was set \( t_0 = 543 \text{ s} \).

Following the recommendations of (Shamaev, 2003), the best conditions for pressing wood with simultaneous drying are carried out at close temporal relaxation values of dehydration to and lag time \( t_0 \) and therefore in the counting process when determining deformations \( \varepsilon_{sh} \) in accordance with relation (6) we withstand \( t_0 = t_0 \). With an increase in the pressing time \( t \) at the first stage, a decrease in the moisture content \( W \) (Fig. 3a) of wood by an amount...
At the same time, the relative compaction of wood \( \rho \) in the direction of compression is determined both by the value of the total longitudinal strain \( \varepsilon \) and additional deformations of the temperature expansion \( \varepsilon_T \) and shrinkage \( \varepsilon_{sh} \):

\[
\rho = 1 + \varepsilon - \varepsilon_T + \varepsilon_{sh}.
\]  

(21)

As we see, only in two cases, the relation (21) coincides with the classical relation (1): either the temperature \( T \) is insignificant and, as a result, \( \varepsilon_T = \varepsilon_{sh} = 0 \) or the temperature deformations are significant and tend to shrinkage deformations, i.e. \( \varepsilon_T \approx \varepsilon_{sh} \neq 0 \). In all other cases, when \( \varepsilon_T \neq \varepsilon_{sh} \), in the tangential direction the condition should be:

\[
\varepsilon_T = \mu \varepsilon - \varepsilon_T = \varepsilon_{sh}.
\]  

(22)

Thus, data analysis in Fig. 2 and Fig. 3 allows us to conclude that the first stage of pressing and dewatering with simultaneous drying of wood samples is well described by linear deformation processes and the corresponding linear dependencies.

We investigate the fulfillment of condition (22) over the entire time interval of dehydration, i.e. Let us compare the behavior of the dependences \( \varepsilon_t(t) \) and \( \varepsilon_{sh}(t) \).

Fig. 4a shows the dependences of the change in total transverse deformation \( \varepsilon_t \) and deformation of shrinkage \( \varepsilon_{sh} \) on time \( t \). As you can see, during the first stage of deformation of wood in a given mode, condition (17) does not hold and the inequality \( \varepsilon_{sh} > \varepsilon_t \) holds, and by the time of completion of the stage \( t = \tau = 60 \) s the excess reaches 39%.
However, the second stage of pressing and drying the layer $h$ of the wood sample is characterized by a reduction in the difference in deformation rates $\varepsilon_t$ and $\varepsilon_{sh}$ and by the time the stage is completed, condition (22) is fully met (Fig. 4b).

In Fig. 5 by analogy with the data, Fig. 3 shows the graphs of changes in humidity and relative compaction of a given layer of wood during both stages with the observance of the pressing condition (22).

Comparative analysis of data in Fig. 3 and Fig. 5 shows that the linear nature of the dependences $W(t)$ and $\bar{\rho}(t)$ established for the first stage of deformation has changed to the general logarithmic law for describing these processes throughout both stages with satisfactory approximation figures of the calculated data (the coefficients of determination are 0.87-0.9).

In one cycle (step) of pressing and dewatering ($t_o = 543$ s), the relative compaction reached $\bar{\rho} = 1.085$, i.e. the density of wood within the layer $h = 1.4$ mm increased from 760 to 825 kg/m$^3$, and the humidity decreased from 50 to 49.15%.

Next, it is necessary to produce a new cycle of pressing, dewatering and drying in accordance with the accepted technology of work and, ultimately, to obtain a sample of wood with given indicators of density and humidity.

The nature and intensity of deformation of the samples depend on a number of source data, namely: the conditions for placing the blanks in the molds, their initial moisture $W_o$, the concentration of the urea solution $C$ and the increase in its mass $Q$, the methods of creating an overpressure $P$, the level of the specified temperature field $T$, and also on the shape and size of pressing tools (dies) in the process of their impact on solid wood.

The main technological parameters affecting the final indicators of modified wood are: 1) pressing speed $V_n = h/\tau$, where $h$ is the amount of movement of the stamp for a certain time interval $\tau$, providing the necessary amount of pressing pressure $P$; 2) drying temperature $T$; 3) the final processing time $t_f V_n V_p$.

As a criterion for the efficiency of technological processes, let us take the final density $\rho$ of the sample (or its relative compaction:

$$\bar{\rho} = \rho/\rho_0 \quad (23)$$

where $\rho_0$ is the initial density of the impregnated wood before pressing) at a given moisture content $W$, i.e. $\bar{W}$ degree of required dehydration. All other indicators – compressive strength, hardness, stiffness, and other correlation ratios are related to the parameters $\rho$ and $W$.

The value of $\rho_0$ depends on the density of natural dry wood $\rho_n$, as well as on $W_o$, $C$ and $Q$ (Shamaev, 2003). In particular, for birch samples with $\rho_o = 550-570$ kg/m$^3$ after their impregnation in 20-30% urea solutions and the achievement of humidity $W_o = 40-50\%$, $\rho_0 = 720-760$ kg/m$^3$.

The range of changes in the end indicators $\rho$ and $W$ is quite wide depending on technological tasks and goals (production of sleepers, pillars, mine stand, etc.) and on average is: for the parameter $\rho$ from 900 to 1200 kg/m$^3$, for $W$ from 2 to 10%.

To achieve these parameters, the technological parameters vary in very wide intervals: the pressing speed $V_n$ in the range from 0.2 to 20 mm/min and the corresponding pressing pressure $P$ from 0.5 to 2.5 MPa, temperature $T$ from 110 to 170°C, time processing $t_f$ – from 2 to 20 hours. Such significant boundaries of the intervals determine the need to optimize these parameters in order to achieve the specified indicators for obtaining modified wood. $V_n V_p$.

A model of pressing rectangular samples of wood impregnated and saturated with moisture under the action of a flat die $I$ without the use of any molds is shown in Fig. 1a, where it is assumed that pressing a layer $h$ of a wood sample 2 with height $H$ and width $b$ is carried out across the fibers in the radial $(r)$ direction, which coincides with the direction of action of the force $P$ with simultaneous drying in a given field.

Under the action of a compressive load $P$, the layer $h$ directly under the press experiences a vertical $q_v$ and a horizontal $q_h$ of pressure (Shapiro et al., 2008) (Expression 4).
Calculations of the parameters of pressing and dewatering a layer of wood of size $h$ during the time in the field of high temperatures $T$ were carried out for the conditions of deformation across the fibers in the radial direction $r$ under a flat press of heated wet birch samples impregnated with 20-30% aqueous urea solution, with the following initial data: pressing speed $V_p = 1.4$ (mm/min); $\alpha = 33.7 \times 10^{-6}$ (1/deg), where $\alpha$ is the coefficient of linear expansion of wood, which characterizes the increase in the unit length of the material when heated by 1°C; $W_o = 50\%$, $\rho_o = 760$ kg/m$^3$; $E = 126.9$ MPa; $\nu = 0.3$, $T = 140^\circ$C, $b = H = 0.13$ m, shrinkage coefficient $K_{sh} = 0.26$, the cross-sectional area of the micro perforations is $s = 0.00264$ mm$^2$, the dynamic viscosity of the fluid is $\gamma = 0.13417$ MPa·s.

It was established that in the process of moving the press from $h = 0$ to $h = 1.4$ mm, the linear behavior of the dependences $q_v(h)$ and $t_o(h)$ is observed, and at the time $\tau = 60$s, the pressing pressures $q_v = 1.506$ MPa are achieved, which are kept constant during the optimal period, the dehydration time is $t_o = 543$ s. During this period, within the limits of the layer $h$, the compaction of the mass if $\rho$ increases and its humidity $W$ decreases in accordance with the data presented in Fig. 5.

The analysis of logarithmic curves indicates the existence of two sections – branches of intense and asymptotic damping of the exponents $\rho$ and $W$, and the conjugation of these branches occurs at the moment of time $t \approx 180200$s. Thus, in one pressing cycle ($N_c = 1$) within $t_o = 543$c, the relative compaction reached $\rho = 1.085$, the density of wood within the first layer $h = 1.4$ mm increased from 760 to 825 kg/m$^3$, and the humidity decreased from 50 to 49.15%.

Outside the layer $h$ at some distance $r \geq h$, the pressing pressure $q_v$ causes in the wood massif the action of vertical $\sigma_r$ and tangential $\sigma_\theta$ stresses equal to

$$
\sigma_r = \frac{q_v}{(r/h)^n}
$$

(24)

The exponent $n$ in formula (24), as a rule, 2 is assumed to be 2 when solving the Boussinesq problem (Shapiro et al., 2008), thereby assuming that the voltages decay quite intensively with increasing distance $r$.

However, the nature of the attenuation of stresses for environments with internal friction, and these should include an array of wood, it is better to describe the coefficient $n$, equal to:

$$
n = \chi - \mu,
$$

(25)

where $\chi = 3$ for a spherical stress front, $\chi = 2$ for a cylindrical one, and $\chi = 1$ for a flat one (Shemyakin, 1969; Mosinets & Abramov, 1982).

Thus, to assess the stress-strain state of an array of wood under the action of a flat stamp, we take $n = 1-\mu$. In particular, for $\nu = 0.3$ and $\mu = 0.43$, the value of $n = 0.57$, i.e. the attenuation of the flat stress front in the sample material with distance from the surface of the press is rather slow.

In accordance with (24), when $n = 1-\mu$, the vertical stresses $\sigma_r$ acting in the wood mass outside the layer $h$ in the $r$ direction are estimated as the relative distance $r = r/h$ from 1 to 4 varies, the attenuation pattern of which is shown in Fig. 6.

Modeling of the process of pressing and dewatering wood in the field of high temperatures has shown that to ensure optimal conditions for the process of deforming the wood, it is necessary that the speed of pressing corresponds to the temperature level.

In Fig. 7 shows the dependence $V_n$ on $T$, which indicates a non-linear increase in the speed of pressing with an in-
crease in the heat treatment temperature of the sample, and
the most intensive growth is observed when the level of heat
treatment is reached $T \geq 140^\circ$C. $V_nV_p$

On the second cycle of processing a wood sample ($N_c = 2$), maintaining the pressing pressure constant and equal
to $q_v = 1.506$ MPa, the mathematical model reproduces all
the above operations and calculations, however, the fact that
within the next layer $h$ the array was previously subjected to
general deformations $\varepsilon$ is taken into account from the action
of compressive stresses $\sigma_r$, which had an additional impact
on the process of pressing and dehydration.

In Fig. 8 shows the dependence of the strain $\varepsilon$ on $\sigma_r$.

Fig. 8. The dependence of the total deformation of wood
from the existing compressive stresses

Based on the data obtained in the study of the stress-
strain state of the array within the next layer $h$ for the initial
data: $\bar{r} = 2$, $q_v = 1.506$ MPa and $\mu = 0.43$ using formula (22),
we obtain the value of compressive stresses $\sigma = 1.015$ MPa,
which upon completion the first cycle ($N_c = 1$) determine the
effect of additional common deformations of the array element
$\Delta\varepsilon = 0.0103$ and its corresponding additional sealing
$\Delta\rho = \Delta\varepsilon + 1 = 1.01$.

Thus, the total value of the relative compaction of the
second layer will be $\bar{\rho} = 1.085 + \Delta\varepsilon = 1.095$.

Studies of pressing the array in subsequent cycles allowed us to establish the linear character of the behavior of the function $\bar{\rho} (N_c)$ shown in Fig. 9a:

$$\bar{\rho} = 1.075 + 0.01N_c$$

(26)

Similarly, studies on the decrease in humidity $W$ of the
next layer of the array with increasing number of cycles $N_v$
pressing and dehydration (Fig. 9b) allowed us to obtain the dependence:

$$W = 50 - 1.0224N_c$$

(27)

In particular, with (27) established as $W = 10\%$, $N_c$ is 39,
which corresponds to the sample processing time $t_c = N_vt_o =

39543/3600 = 5.9$ hours, after which with (26) we estimate
mass consolidation achieved $\bar{\rho} = 1.465$ or its final density $\rho$
$= 1113$ kg/m$^3$.

If necessary, provide lower values of humidity, for example,
$W = 5\%$, ratios (26) and (27) give the following calculated parameters: $N_c = 44$, $t_c = 6.6$ hours, $= 1.515$ or $\bar{\rho} = 1152$ kg/m$^3$.

Thus, the requirement to reduce the final moisture con-
tent of the sample by two times (from 10 to 5%), other things
being equal and very close (less than 3.5%), its compaction
results in a slight increase in processing time (by 11.5–12%).

This conclusion generally corresponds to the recom-
menations (Grigorev et al., 2019), where the scope of ap-
lication of a modified birch-based destam (urea-plasticized
wood) sample determines a wide range of changes in the fi-
nal density $\rho = 800$-1200 kg/m$^3$ with an extremely narrow
range of changes in the final humidity $W = 4.8$-5%.

As the simulation results showed, the factor of tempera-
ture of heat treatment of wood, taking into account the in-
terrelation of parameters $T$ and $V_n$ has a significant impact
on the values of $t_v$ and $N_v$. The revealed regularities of the
pressing and dehydration processes, as well as the obtained
correlation ratios with rather high values of the coefficient of
determination ($R^2 \geq 0.9$), made it possible to calculate the fi-
n al technological parameters with variations in humidity $W$, compaction $\tilde{\rho}$ and temperature $T$. 

Statistical processing of the data allowed us to establish the linear multiple regression equations:

$$tk(\tilde{\rho}, W, T) = (k_1 W + k_2) (k_3 T + k_4)$$

(28)

And compaction:

$$\tilde{\rho} = k_5 T + k_6 W + k_7.$$  

(29)

To determine the conditional extremum of the function (28) along the surface of the bond (29), we searched for the extremum of the Lagrange function

$$L(\tilde{\rho}, W, T, \lambda) = (k_1 W + k_2 \tilde{\rho})(k_3 T + k_4) - \lambda (k_5 T + k_6 W + k_7)$$

(30)

where $\lambda$ is the Lagrange multiplier.

As applied to the accepted conditions for calculating the value of the coefficients $k_i$, the composition is $k_1 = -0.561; k_2 = 7.98; k_3 = -0.0186; k_4 = 3.607; k_5 = 0.0032; k_6 = 0.0135; k_7 = 0.882$.

Given the objective function $t \rightarrow \min$, the following solution of the system of equations is reached:

$$\frac{\partial L}{\partial \tilde{\rho}} = k_2 (k_3 T + k_4) - \lambda = 0$$

$$\frac{\partial L}{\partial W} = k_1 (k_3 T + k_4) - \lambda k_6 = 0$$

$$\frac{\partial L}{\partial T} = \lambda k_5 + k_4 (k_1 W + k_2 \tilde{\rho}) = 0$$

$$\frac{\partial L}{\partial \lambda} = k_5 T + k_6 W + k_7 - \tilde{\rho} = 0$$

With technological limitations:

$$1.2 \leq \tilde{\rho} \leq 1.8; 2 \leq W \leq 12; 110 \leq T \leq 170$$

(31)

(32)

As a result, it was established that the point of conditional extremum of function (28), in particular for the calculated coefficients $k_i$, is the $M_0$ point (1.561; 10; 170), and the required and sufficient sample processing time was $t_c = 3.7$ hours. When this is achieved, the density of wood $\rho = 1186$ kg/m$^3$ and its humidity $W = 10\%$. For comparison and analysis of the results obtained, we turn to the technology for producing thermoplastic wood, where as a result of preliminary dehydration of blanks up to 40%, their warming up to 132°C (urea to biuret transition temperature) and heat treatment at $T = 170°C$, pressing under pressure $q_v = 2.5$ MPa for 2 hours provided a decrease in humidity to 8–12% and density to 1200 kg/m$^3$.

Thus, the developed mathematical model allows at the stage of preliminary theoretical estimates to determine the optimal parameters of the process of compaction of impregnated wood in the process of its pressing, dewatering and drying.

**Conclusions**

The regularities of the change in time of the flow rate of the fluid in the process of pressing samples are established and it is shown that the period of intensive decline of this indicator is 58-85% (average 70-72%) of the period of its asymptotic decline. The nonlinear nature of the growth rate of the sample was revealed as the temperature of its heat treatment increased, with the most intense growth rate being observed when the temperature level exceeded 140°C. The degree of influence of the number of pressing cycles on the development of the process of compaction of plasticized wood in the process of its dehydration is shown. Thus, with a given final moisture content of wood equal to 10%, the required number of pressing cycles reaches 39, which corresponds to the sample processing time of 5.9 hours and achieve a degree of compaction of 46.5%. As a result of the implementation of the developed mathematical model, an equation of linear multiple regression is obtained depending on the sample processing time on the required values of their compaction and humidity in a given temperature field, which forms a reliable theoretical basis for solving various optimization problems of the technological parameters of the pressing and dewatering plasticized wood samples.
